ABSTRACT

Aims: To find out the status of the major plant nutrients important for plant growth and development in selected areas in Tanzania.

Place and Duration of Study: The physical chemical soil properties survey was conducted in Msagali and Chipogolo proposed irrigation schemes, Mpwapwa District, Dodoma Region, in Tanzania during the dry season of 2003.

Methodology: Before sampling, the study areas were divided in to twenty two (22) pedogeomorphic units or soil types using pedogeomorphic approach. Thirty soil samples were collected from each pedogeomorphic unit at a depth of 0 – 20 cm in a zigzag manner. The collected soil samples were bulked, homogeneously mixed, and sub-sampled to obtain a kg of a representative composite sample, filled in a plastic bag and labelled. The composite soil samples were sent to Selian Agricultural Research Institute (SARI), Arusha, Tanzania, air dried and ground to pass through a 2 mm-sieve after which they were analysed for physical chemical characteristics leading to the determination of the soil fertility status by means of these major mineral elements.

Results: The results showed variations in fertility status in the selected sites of each scheme. Based on guidelines of soil mineral elements contents established elsewhere, the results showed that the soil had high soil pH (8.1) and excessive Na+ (6.1 cmol (+).kg⁻¹ soil) in 30.9% of the total surveyed area (263.5 ha) in Msagali. Crop production was also slightly constrained by sodicity (ESP = 9.6%) in 73.1% of the total area (130.3 ha) surveyed in Chipogolo and very strongly (ESP = 27.9%) in 55.8% of the total surveyed area in Msagali. The results also showed that total N and Organic Manure (OM) were low, ranging from 0.2 - 1.0 g.kg⁻¹ and 2.3 - 11.7 g.kg⁻¹, respectively. Available P was rated as low to medium and ranged from 1.01 – 5.13 mg P.kg⁻¹ in all sites (i.e. Msagali and Chipogolo). Mg were rated as low (1.0 – 3.2 cmol (+).kg⁻¹ soil.) in 26.9% of the area surveyed in Chipogolo and low in 18.4% of the surveyed area in Msagali ranging from 0.6 – 6.5 cmol (+).kg⁻¹ soil. Results have also showed that of the total surveyed area, 63.7% in Chipogolo and 18.4% in Msagali have low Cation Exchange Capacity (CEC) with values <12 cmol (+) kg⁻¹. C:N ratio in 63.2% the total area surveyed in Chipogolo was of good quality (i.e. C:N between 8 – 12) suggesting ideal conditions for plant growth compared with 36.8% of the total study area in Chipogolo and all the studied sites in Msagali. Our results have indicated Ca: Mg ratios to be less than the suggested guidelines in 36.8% of the total surveyed area in Chipogolo suggesting that plants would probably respond to the addition of Ca or Mg in such areas.

Conclusion: The overall information from this study could be used in soil and fertiliser management studies to establish nutrient requirements for different crops grown in these
1. INTRODUCTION

In Mpwapwa district, Dodoma Region, Tanzania, farmers have realized that huge profit margins can be achieved through crop diversification including rice (Oryza sativa L.) cultivation. The district, one of the five districts in Dodoma Region, is among the potential areas in Tanzania which practise both rainfed and irrigated agriculture. It is estimated that agricultural sector contributes about 48% of the total District Gross Domestic Product (GDP). The district has a total area of 223,000 ha potential for agriculture of which more than 5,991 ha (2.7%) are potential for irrigation development. However, only 2,891 ha (48.3%) are currently irrigated by water from different sources including rainwater harvesting, rivers and storage dams. Some of the important crops cultivated in these areas include: Bambara groundnut (Vigna subterranea (L.) Verdc.), cassava (Manihot esculenta), cowpea (Vigna unguiculata L.), groundnuts (Arachis hypogea L.), maize (Zea mays L.), pearl millet (Pennisetum glaucum), onions (Allium cepa L.), sorghum (Sorghum bicolor L.), sunflowers (Helianthus annuus), sweet potatoes (Ipomoea batatas) and rice (Oryza sativa L.).

Due to increasing consumption of rice in the region, majority of farmers are now engaged in intensified irrigated rice cultivation in order to address the food crisis within and outside the region. Just as in other tropical areas, the selected areas for rice cultivation in Mpwapwa district are challenged by negative mineral elements balances essential for plant growth and development [1; 2]. These challenges include excessive leaching, soil degradation, non-replenishment of the removed plant nutrients and low purchasing power to replenish the depleted mineral elements [3; 1; 4].

Due to complex interactions between soil and crop management, farming systems and soil fertility, production of both food and cash crops have declined, thus, threatening food security in these areas. For example, the current rice and maize grain yields in these irrigation schemes is very low, 1.0 – 1.5 t ha\(^{-1}\) [1; 6]. As yet no information is available presently, there is no research information to quantify and study the influence of soil fertility factors and their effect on crop yields. However, studies in similar environments of continuous land cultivation without proper management practises in some areas of Africa have shown soil fertility decline [7; 8; 8, 9]. Therefore, the decrease in crop yields and its impact on yields and household food security [10; 11; 12; 13] in many areas of Mpwapwa district forebode decline in soil fertility.

Key indicators on soil fertility have previously been reported as soil pH, soil organic carbon (OC) or soil organic matter (SOM); cation exchange capacity (CEC); exchangeable bases (EB), salinity (S) and sodicity status (SS) and the amount of extractable N, P, K, Mg, Ca and Na [14;15]. These indicators are realistic in predicting plant growth and development. Hence there is a need for regular and systematic evaluation to establish their levels in the soil so as in order to achieve sustainable crop productivity in cropping systems. If unchecked, their limitation may result in complex mineral elements imbalances, consequent poor soil quality, and decline in soil productivity and crop yields [16; 17].

Thus, assessment and understanding of the soil fertility status based on the aforementioned attributes will not only provide strategies for soil fertility management and land development, but also will provide input into the design and planning of crop nutrition packages in the study areas. To date, studies on soil fertility status survey studies in Tanzania are very

Keywords: [calcium, cation exchange capacity, crop production, excessive sodicity, fertility constraints, management practices, soil organic matter, survey]
The objective of this study was to assess the soil fertility status in the selected irrigation schemes of Mpwapwa District, Dodoma Region, Tanzania.

2. MATERIAL AND METHODS

2.1 DESCRIPTION OF STUDY AREA

The irrigation schemes of Chipogolo and Msagali are located in Mpwapwa District, Dodoma Region, in the Central part of Tanzania. Specifically, Chipogolo is located at 6°15’S and 35°30’ E, 100 km South West of Mpwapwa town at an altitude of 100 m a.m.s.l. Msagali is located at 6°15’S and 36°25’ E, 16 km South West of Mpwapwa town at an altitude of 98.5 m a.m.s.l. These schemes are generally on a plain or piedmont landscape. The climate of the two schemes is characterised as hot semi-arid according to Köppen’s classification [19]. The rainfall pattern in the district is characterised by 2 intermediate months and 10 dry months (see Table 1). The rainfall pattern is unimodal with one rainy season from November through May. Its distribution is unreliable and there is a risk of drought in January and March (Table 1). The driest months are between June to October with no rains at all occur between the months of June and October, where there is completely no rain as shown in Table 1. The annual rainfall is 642 mm.month⁻¹ while annual evapotranspiration is 2,147 mm.month⁻¹. The mean monthly temperature in these schemes is between 21.8°C - 26.7°C while the mean annual temperature is 24.6°C. There is slightly cooler period from May to July marked by the onset of the winds which continues up to October. Sunshine hours range between 7.1 - 9.9 hrs. Potential evaporation at Dodoma station as computed by Penman equation is in the range of 145 mm.m⁻¹ (February) to 254 mm.mnth⁻¹ (October) or 2,147 mm per annum. Relative humidity (RH) is between 61.1% (November) and 78.4% (April). Annual RH is 67.8%. The climatic data representatives for Chipogolo and Msagali schemes are summarized in Table 2.

2.2 SOIL SAMPLING

Before sampling, the study areas were divided into twenty two (22) pedogeomorphic units or soil types using pedogeomorphic approach [20]. Thirty soil samples were collected from each pedogeomorphic unit at a depth of 0 – 20 cm in a zigzag manner. The collected soil samples were bulked, homogeneously mixed, and sub-sampled to obtain a kg of a representative composite sample, filled in a plastic bag and labelled. The composite soil samples were sent to Selian Agricultural Research Institute (SARI), Arusha, Tanzania, air dried and ground to pass through a 2 mm-sieve after which they were analysed for physical chemical characteristics leading to the determination of the soil fertility status by means of these major mineral elements.

2.3 SOIL PHYSICAL-CHEMICAL CHARACTERISATION

Particle size analysis was determined by the Bouyoucos hydrometer method [21]. Organic carbon (OC) was done by Walkley and Black wet acid dichromate digestion method [22]. Soil organic Matter (SOM) was calculated as 1.72 x % OC [23]; pH (water) was determined by a pH meter using 1:2.5 soil to water ratio as described by [24] whereas total N was done by semi-micro Kjeldahl digestion [25] followed by ammonium distillation and titrimetric determinations. Exchangeable bases (Ca, Mg, K, Na) and CEC determination depended on soil pH. In soils with pH < 7.5, subsequent percolation with 1M ammonium acetate (NH₄OAC) at pH 7, ethanol and acidified 1MKCl in the first percolate [26]. For soils with pH > 7.5 and high

¹Ministry of Agriculture Food and Cooperatives, Directorate of Irrigation, P.O. Box 9192, Dar es Salaam, Tanzania; email: joachimmakoi@yahoo.com; Cell: +255 (0) 762 293 254
carbonates contents, the method recommended by [27] was followed. Determination of K and Na was done with flame photometer, Ca and Mg by atomic absorption spectrophotometer [28]. Cation exchange capacity (CEC) was done following the method by [28]. Electrical conductivity (EC) was measured by a conductivity meter from the soil solution directly following the procedure described by [29]. Available P was extracted spectrophotometrically [30] by reacting with ammonium molybdate using ascorbic acid as a reductant in the presence of antimony, as in [31]. The total exchangeable bases (TEB) were obtained as the sum of exchangeable Ca, Mg, K and Na. Percent base saturation (%BS) was obtained by dividing TEB by CEC and then multiplied by 100 [32]. Page et al., 1982. Exchangeable sodium percentage (ESP) was obtained by dividing total exchangeable sodium by CEC, and then multiplied by 100. The K:TEB was obtained by dividing K by TEB.

### 3 RESULTS AND DISCUSSION

#### 3.1 SOIL REACTION

Results from the survey showed that pH of the top soils ranged from 6.1 - 7.1 in Chipogolo and 73.1% (i.e. 95.3 ha) of the total surveyed area (130.3 ha) was rated as mildly acidic to as very slightly acidic acid to slightly acid and 35 ha (i.e. 26.9%) was rated as neutral (Tables 3 and Table 5). Soil pH reaction of the top soils in Msagali ranged from 6.9 - 8.1 and 37.5% of the total surveyed area (263.5 ha) was rated as very slightly acid, 31.7% as mildly alkaline and 30.9% as moderately alkaline (Tables 3 and 5) [33]. Soil pH is an important indicator in assessing soil fertility and its environment. For example, the normal pH range for optimal mineral elements availability for most crops is 6.0 - 7.5 [34; 35]. However, 30.9% of the surveyed area in Msagali (i.e. MSAG-Pa3) had a soil pH of 8.1 rated as moderately alkaline (Table 3, 5) [33] and mineral elements deficiency such as P, Ca, Fe, Cu, Zn, Mn and Mo are likely to occur [36; 37; 38]. Furthermore, unfavourable plant growth conditions such as severe root damage, shallow rooting, poor root development, susceptibility to drought and poor use of subsoil mineral elements have been reported in such pH range [39; 40]. Collectively, the constraints associated with alkaline conditions may threaten the yield potential particularly in Msagali study area.

#### 3.2 TOTAL SOIL ORGANIC MATTER AND ORGANIC CARBON

Soil organic matter (SOM) content in the study area ranged from 2.3 - 11.7 g.kg⁻¹ in topsoil (Table 3) and was rated as very low (Table 5). Since SOM content was calculated from soil organic carbon [23], these parameters have had the same trend. It is generally accepted that a threshold for SOM in most soils is 34 g.kg⁻¹ below which decline in soil quality is expected to occur [41]. Soil organic matter was below the proposed threshold values in all the sites used in this under study, suggesting a decline in soil quality (Tables 3, 5). It is, therefore, apparent that there is a need to replenish the SOM using resources such as crop residues and manure for maximum crop yields. Understanding the SOM status before any development interventions are undertaken is of vital importance because such materials have been reported extensively it is known extensively to play a key role in the improvement of soil physical and chemical properties. These properties include structural stability, porosity, mineral elements availability (i.e. N, P and S); cation exchange capacity [42; 35; 43; 44; 45]; and soil moisture and nutrient holding capacity [14]. SOM has also been reported to have great impact on improving irrigation efficiency for sustainable land productivity; to enhance productivity and environmental quality; to reduce the severity and costs of natural

---

1 Ministry of Agriculture Food and Cooperatives, Directorate of Irrigation, P.O. Box 9192, Dar es Salaam, Tanzania; email: joachimmakoi@yahoo.com; Cell: +255 (0) 762 293 254
phenomena, such as drought, flood, and disease; to reduce atmospheric CO$_2$ levels that contribute to climate change [46; 47; 48; 49].

3.3 TOTAL N

Total nitrogen (TN) status in the study area ranged from 0.2 - 1.0 g.kg$^{-1}$ in Chipogolo and 0.3 – 0.4 g.kg$^{-1}$ in Msagali (Table 3) and was rated as very low (Table 5). According to [33] guidelines, the proposed value for most crops in Tanzania is 2 g N.kg$^{-1}$ soil. The results show that all the surveyed sites had total N below the threshold value (< 2 g.kg$^{-1}$) and was rated as very low (Tables 3, 5). The observed low N in these areas may be attributed to, amongst others, low SOM content which is greatly influenced by microbial activity in the soil [50] and high soil pH which could lead to N loss through ammonia volatilisation [51]. In our study, soil samples with relatively higher N levels were obtained from the relatively organic enriched soils. So, any activity envisaged to improve the soil pH, SOM and microbial activities can, consequently, lead to an increase in the %N in the soil. Inadequate amounts of N in the soil are the primary factor that limits plant growth and development in many parts of the world [52; 53] suggesting short- and long-term interventions. Practices such as choice of cropping systems involving legumes with N$_2$ fixation capability, the use of artificial acidified nitrogen fertilisers, animal manure or composts are some of the means by which N input into the soil can be effected.

3.4 C:N RATIO

The C:N ratio showed no clear relationship with the soil texture in our study. The C:N ratio ranged from 12 to 20 suggesting that the study area has a moderate to good quality SOM (Tables 3, 5) [33]. It is generally accepted that C:N ratios between 8 and 12 are considered to be the most favourable. In this study, 63.2% of the total area (i.e. 130.3 ha) in Chipogolo (CH-Pi2 and CH-Pa1) have good quality SOM implying a relatively fast mineralisation of N from the organic materials. For example, higher C:N ratios greater than 23 [56] have been shown to favour slow degradation of residues by the associated micro-organisms [57], higher immobilisation effects [56] and limited N in the soil that may lead to reduced crop yields [54; 55; 56]. The observed C:N ratio status in 63.2% of the surveyed area in Chipogolo suggests ideal conditions for plant growth since in such situations mineralisation in the soil is greater than immobilisation, compared with 36.8% of the total study area in Chipogolo and all the studied sites in Msagali where mineralisation in the soil was lower than immobilisation.

3.5 AVAILABLE PHOSPHORUS

In Chipogolo, the data showed that, phosphorus (P) ranged from 2.31 – 5.13 mg P.kg$^{-1}$ (Table 3) and was rated as low to medium (Table 5). Of the total study area (130.3 ha), 36.8% was rated as having low P (i.e. 2.31 mg P.kg$^{-1}$) and 63.2% was rated as having moderate P availability (i.e. an average of 4.87 mg P.kg$^{-1}$). In Msagali, the data showed that, P ranged from 1.01 – 2.12 mg P.kg$^{-1}$ and was rated as low (Tables 3, 5). Phosphorus is an essential macro-element for plant growth, hence an important soil fertility indicator. Based on the current soil fertility recommendation that uses a critical P concentration of > 7 mg P.kg$^{-1}$ to separate P deficient soils [33], P availability was less than critical range. The observed low values of P could partly be attributed to fixation into unavailable forms due to high soil pH especially so in areas such as Msagali (Tables 3, 5). For example, in alkaline soils, calcium phosphates (Ca$_3$(PO$_4$)$_2$ are less soluble, hence high P retention capacity and consequently low P availability [57].

3.6 EXCHANGEABLE BASES (K, Mg, Ca)

1Ministry of Agriculture Food and Cooperatives, Directorate of Irrigation, P.O. Box 9192, Dar es Salaam, Tanzania; email: joachimmakoi@yahoo.com; Cell: +255 (0) 762 293 254
Results in this study showed that potassium (K) levels in the soil ranged from 0.78 - 7.68 cmol (+).kg⁻¹ soil in Chipogolo and was rated as medium in 26.9% and high or very high in 73.1% of the total area (i.e. 130.3 ha) surveyed. In Msagali, K ranged from 0.33 - 0.55 cmol (+).kg⁻¹ soil, and was rated as low in 13.3%, medium in 49.3% and high in 37.4% of the total area (i.e. 263.5 ha) surveyed (Tables 3, 5). It is generally accepted that response to K fertilisers is likely when a soil has an exchangeable K value of less than 0.2 cmol (+).kg⁻¹ soil and unlikely when it is above 0.4 cmol (+).kg⁻¹ soil [33; 58]. Based on the critical concentrations of exchangeable K values of 0.2 - 0.4 cmol (+).kg⁻¹ soil, the data suggests that K is not a limiting mineral element to crop productivity in the study area [33; 59].

These results also showed that Mg²⁺ content was low to high in the topsoil of Chipogolo area ranging from 1.0 – 3.2 cmol (+).kg⁻¹ soil. In this area, Mg content in 26.9% of the total area surveyed was rated as low, 36.8% as medium and 36.3% as high. Mg was rated as low to very high in the topsoil of Msagali area ranging from 0.6 – 6.5 cmol (+).kg⁻¹ soil and Mg content in 18.4% of the total area surveyed was rated as low, 13.3% as medium and 68.3% as high or very high (Table 3, 5). The recommended value of Mg²⁺ in most crops is 2 cmol (+).kg⁻¹ [60]. The observed low levels of Mg²⁺ in 26.9% of the total area surveyed in Chipogolo and 18.4% of the total area surveyed in Msagali suggest that these areas have insufficient Mg²⁺ supplies for crop growth. Mg is required by a large number of enzymes involved in energy transfer, particularly those utilizing ATP; a constituent of the chlorophyll molecule; is required for the normal structural development of the chloroplast; as well as other organelles such as the mitochondrion [61; 62; 63; 64]. Thus, it is expected that Mg deficiency would have damaging effects on photosynthesis and respiration leading to poor crop yields. As such measures should be undertaken to ameliorate such deficiencies for crop development.

The exchangeable Ca²⁺ in the topsoil of the Chipogolo study area ranged from 3.9 - 9.7 cmol (+).kg⁻¹ soil. The data showed that of the total area, 63.2% was rated as medium and 36.8% as high (Tables 3, 5). Likewise in Msagali, 18.4% was rated as medium, 30.9% as high and 50.7% as very high (Tables 3, 5). [65] proposed that in most crops, the recommended threshold level of Ca²⁺ is 5 cmol (+).kg⁻¹. Calcium deficiency occurs frequently in a range of crops when exchangeable Ca concentration is less than 1 cmol (+).kg⁻¹ [66; 67]. It is generally acknowledged that field conditions that limit Ca²⁺ uptake produce lower crop yields than crops grown with adequate Ca²⁺ [68;69;70;71]. The medium to very high levels of Ca²⁺ in the study areas indicates lower bondage of Ca²⁺ to P at relatively lower soil reactions (Tables 3, 5).

3.7 CATION EXCHANGE CAPACITY

The cation exchange capacity (CEC) status in the soil ranged from 3.73 - 36.6 cmol (+) kg⁻¹ (Table 3) and was rated as very low to high (Table 5) [33]. Cation exchange capacity refers to the exchange phenomenon of positively charged ions at the surface of the negatively charged colloids. The higher the CEC, the more capable the soil can retain mineral elements. Studies have shown that soils with CEC values of between 6 - 12 cmol (+) kg⁻¹ are poor in exchangeable bases [33]. Of the total surveyed area, 63.7% in Chipogolo and 18.4% in Msagali had CEC values <12 cmol (+) kg⁻¹. According to [72], soils with low CEC are typically weathered with a low ability to support plant growth with adequate mineral elements such as Ca. It is generally accepted that SOM is responsible for 25 - 90% of the total CEC of surface horizons of mineral soils [73; 74]. The very low or low to medium CEC found in some areas in this study could be related to low SOM (Tables 3, 5). The very low or low CEC values in soils have also been implicated with low yield in most agricultural soils [72]. Any intervention such as applying both manure and the required amount of fertiliser with the aim

---

1Ministry of Agriculture Food and Cooperatives, Directorate of Irrigation, P.O. Box 9192, Dar es Salaam, Tanzania; email: joachimmako@yahoo.com; Cell: +255 (0) 762 293 254
of improving the CEC of the soil is recommended. By doing so, humus content of the soil will increase and, consequently, improve the CEC that may lead to better retention of mineral elements in the soil.

3.8 EXCHANGEABLE SODIUM (Na) OR EXCHANGEABLE SODIUM PERCENTAGE (ESP)

The exchangeable sodium (Na\(^+\)) range from 0.31 - 4.31 cmol (+) kg\(^{-1}\) soil corresponding to ESP values ranging from 5.3 – 9.6% in Chipogolo and from 0.43 - 6.1 cmol (+) kg\(^{-1}\) soil corresponding to ESP values ranging from 4.2 – 27.9% in Chipogolo, Msagali (Tables 3, 5). The critical values of ESP above which most crops are affected are established at 15 [75]. 26.9% of the total surveyed area in Chipogolo had ESP of 5.3 which was below the recommended threshold levels of ESP < 6 rated as non-sodic (Tables 3, 5). However, 73.1% of the total surveyed area in Chipogolo was rated as slightly sodic. In Msagali, 37.4% of the total surveyed area had 6.1 cmol Na (+) kg\(^{-1}\) soil and ESP of 27.9 rated as very high and very strongly sodic respectively. However, 44.2% of the total area was rated as non-sodic and 18.4% as moderately sodic (Tables 3, 5). The medium to very high Na or slightly/moderately sodic to very strongly sodic status observed in this study may probably be related to high evaporation, poor management of irrigation water, lack of drainage systems and low Ca\(^{2+}\) due to high Na\(^+\) concentrations in the exchange complex (Tables 3, 5). Higher Na\(^+\) levels in the soil is associated with decline in net photosynthesis; energy losses for salt exclusion mechanisms; greater decrease in mineral elements uptake; poor NO\(_3\)\(^-\) assimilation required for plant growth; inhibition of vital enzymes and competition with K\(^+\) [76; 77; 78; 79]. The excessive Na\(^+\) in the soil is likely to cause reduced plant growth and development, thus, decreased crop yields [80; 81; 82; 83]. Our results suggest that such sodic soils may require appropriate amendments such as farm yard manure (FYM) and or gypsum to reduce the concentration of Na\(^+\) on the exchange complex, thereafter followed by leaching to replace the soluble Na\(^+\) on the soil colloid, through irrigation or rain water [84; 2] and use of acidifying fertilisers such as sulphate of ammonia to lower the soil pH. Successful results on the use of locally available soil ameliorants, such as gypsum (CaSO\(_4\)\(\cdot\)2H\(_2\)O) as a Ca\(^{2+}\) source and/or organic manure, has been reported in northern Tanzania [2].

3.9 CATION RATIOS

In Chipogolo, the Ca:Mg ratios ranged from 2 to 3.9; Mg:K ratio: from 0.4 to 2.2 and K:TEB ratio: from 11.6 to 30.9% (Table 4). But in Msagali, the Ca:Mg ratios ranged from 2.7 to 13.8; Mg:K ratio: from 1.1 to 14.8 and K:TEB ratio: from 1.2 to 12.3%. According to the established guidelines [33; 85], the recommended optimum ratio of Mg:K for most crops is 1 - 4. However, in areas where K was high Mg was low and vice versa suggesting that these mineral elements are antagonistic. These results indicate that almost all sites have optimal K enrichment sufficient to support plant growth. In relation to Ca:Mg, our data suggests less favourable conditions for most crops. The availability of mineral elements for uptake by plants depends not only upon absolute levels but also on relative amounts of individual elements. It has been suggested that the optimal cation ratio for the growth of most crops in the tropical area is assumed to be equal to 12.7:3:1 for Ca: Mg: K respectively [33]. Although the general trend for Ca: Mg: K doesn’t indicate a good ratio in relation to the established standards, the individual nutrient ratios are more important i.e. Ca: Mg; Mg: K and K: TEB. Research has indicated that the Ca: Mg ratio of 3 - 5 in the topsoil [33] is optimal for most crops and the K: TEB ratio of less that 2% is sub-optimal and may limit crop production. Our results have indicated Ca: Mg ratios to be less than the suggested guidelines in only 36.8%...
of the total surveyed area in Chipogolo suggesting that plants would probably respond to the
addition of Ca or Mg in such areas (Table 4).

4. CONCLUSION

In conclusion, with reference to the established guidelines elsewhere, results from this study
provide soil fertility indicators for major soil elements in the selected irrigation schemes in the
Mpwapwa District, Dodoma Region, Tanzania. Our results suggest that soil pH and
excessive Na\(^+\) in the soil followed by Ca\(^+\), SOM and CEC are the major soil fertility
constraints to crop production in the area. The information from our study could be
incorporated in the soil fertility management of Tanzania thus contributing significantly in the
utilisation of land resources of the Mpwapwa District, Dodoma Region.
