Barotraumatic Orbital Subcutaneous Emphysema

After Nose Blowing: Case Report

Abstract:

Orbital subcutaneous emphysema is defined as the abnormal presence of air within the periorbital soft tissue. It occurs generally as a result of blunt or penetrating facial trauma. Spontaneous barotraumatic emphysema is a very rare entity that generally results due to a sudden increase in the intraorbital pressure. If there is not an obvious visual acuity loss even with high ocular pressure, it is generally managed conservatively. However, prolonged elevation of intraorbital pressure may cause an irreversible, ischemic visual loss secondary to an ischemic optic neuropathy or an acute central retinal artery occlusion. Emergency decompression may be required. Here we are presenting a patient with barotraumatic orbital subcutaneous emphysema, occurring after forceful nose blowing who was managed conservatively without any complications.

Key Words: Orbital emphysema, nose blowing, subcutaneous emphysema, periorbital swelling, emergency department

Introduction:

Orbital subcutaneous emphysema is defined as the abnormal presence of air within the periorbital soft tissue. It occurs generally as a result of blunt or penetrating...
facial trauma. There are a few spontaneous orbital emphysema cases reported in the literature. The mechanism is defined with sudden increase in the intraorbital pressure [1,2,3,4].

Although, the clinical course is mostly benign in nature, emergency decompression is required in some cases [5]. Severe orbital emphysema can cause an irreversible, ischemic visual loss secondary to an ischemic optic neuropathy or to an acute central retinal artery occlusion [6].

Here we are reporting a rare case of barotraumatic orbital subcutaneous emphysema, occurring after forceful nose blowing who was managed conservatively without any complications.

**Case:**

A 33-year-old man presented to the emergency department (ED) with a history of sudden right upper eyelid swelling. He denied any physical trauma to the face or head. Past medical history revealed nothing special and he had no previous facial surgical operations. He was complaining of flu-like symptoms for a few days and he thought that this swelling might have occurred after a forceful nose blowing.

On physical examination, the vital signs were normal. There was minimal tenderness localized at the right side of the periorbital region, and at the upper eyelid. There was marked ptosis at the effected eyelid (Fig. 1). Upper eyelid palpation revealed fine crepitation. There was minimal bleeding through the right nostril which had stopped spontaneously during the examination. The left nostril was clear. On ophthalmological examination visual acuity and intraorbital pressure was normal in both eyes. Extraocular movements were also normal bilaterally. Computed tomography scan showed air over the right orbita (Fig. 2). There was fracture at the orbital
wall. The orbitopalpebral subcutaneous emphysema diagnosed without blunt or penetrating facial trauma.

The patient was treated with a 7-day broad-spectrum prophylactic antibiotic, nasal decongestant and non-steroidal anti-inflammatory drug. Ice-pack application, avoiding of nose blowing or sneezing was also advised. On head and neck surgery and ophthalmology follow-up visits the patient remained asymptomatic and no complications were observed.

All authors declare that 'written informed consent was obtained from the patient for publication of this case report and accompanying images. A copy of the written consent is available for review by the Editorial office/Chief Editor/Editorial Board members of this journal.

**Figure 1:** The patient with right upper eyelid diffuse swelling and ptosis after nose blowing.

**Figure 2-A:** Axial computed tomographic view is showing the right orbital emphysema (white arrow) **B:** Note the suprapalpebral emphysema (white arrow) **C:** Coronal computed tomographic view is also showing the right orbital emphysema (black arrow) and fracture on the medial wall of right orbita (white arrow) **D:** Note the ethmoid sinus lateral fragment fracture (black arrow)
Discussion:

The medial orbital wall is formed partly by the frontal process of the maxilla, the lacrimal bone and the lateral wall of the ethmoid bone, the lamina papyracea. The lamina papyracea is the weakest point of the medial orbital wall. It has been reported
as the most common site of pure orbital fractures and passage of air from the para-nasal sinuses [7].

Orbital emphysema is not infrequent after blunt or penetrating facial and orbital traumas. But rarely as in our case, might intraorbital barotrauma be the sole mechanism that results in the subcutaneous air. The intraorbital pressure rise can be observed during nose blowing, sneezing, coughing, vomiting, diving or travelling by plane [1,2,3].

In our case nose blowing especially by blocking of one nostril probably results in intranasal pressure elevation, and the pressure reflected directly to the orbital wall. Chiu and colleagues defined that the barotrauma is responsible from a possible defect in the lamina papyracea which is the thinnest part of the orbital wall. After the injury, the air in the paranasal sinuses is thought to enter the orbital, subconjunctival, subcutaneous planes [4].

Subcutaneous orbital emphysema is a relatively benign condition that generally results in cosmetic concerns in patients for a few days. Conservative treatment is usually the choice of treatment [8]. Although the role of prophylactic antibiotics is unclear, in recent reports the authors suggest for a short time [4]. Prolonged elevation of intraorbital pressure may cause an irreversible, ischemic visual loss secondary to an ischemic optic neuropathy or an acute central retinal artery occlusion. Ababneh reported a case with elevated intraocular pressure (26mmHg) who was managed with topical antiglaucoma drug and lubricating eye drops. The patient’s visual acuity in the effected eye was also diminished as the author declared (1).

However some authors reported cases with elevated intraocular pressure required invasive decompression. Garcia and friends reported a severe orbital emphy-
sema case required emergency needle decompression [5]. Shah also reported a case with visual acuity loss that was managed with simple underwater drainage of trapped air by 24-gauge needle (9).

**Conclusion:**

Emergency physicians should be suspicious about the diagnosis of spontaneous fracture of orbital walls when evaluating the patients with ptosis and upper eyelid swelling without trauma. Subcutaneous orbital emphysema cases with normal ophthalmologic examination can be managed conservatively with close follow-up.
